Received 23 February 2006; revised 3 January 2007; accepted 17 January 2007; published 24 April 2007.

[1] Primary productivity and the associated uptake of atmospheric carbon dioxide in the Southern Ocean (SO) is thought to be generally limited by bioavailable iron (Fe). Two sources of Fe for the surface waters of the SO have been proposed: (1) oceanic input of nutrient-rich (i.e., Fe) waters from upwelling and lateral flows from continental margins; and (2) atmospheric input from the deposition of mineral dust emanating from the arid regions of South America and Australia. In this work, analysis of weekly remotely sensed sea surface temperature (SST), ocean chlorophyll *a* content [Chl *a*] and model-derived atmospheric dust-Fe fluxes are used to identify the predominant source of Fe during phytoplankton blooms in the surface waters of the south Atlantic Ocean between 40°S and 60°S. The results of our study suggest that oceanic source through upwelling of nutrient-rich waters due to mesoscale frontal dynamics is the major source of bioavailable Fe controlling biological activity in this region. This result is consistent with the idea that acidification of aeolian dust prior to its deposition to the ocean may be required to solubilize the large fraction of mineral-iron and make it bioavailable.

1. Introduction

[2] The availability of iron (Fe) may control primary productivity in much of the world ocean, particularly in high-nitrate low-chlorophyll (HNLC) regions [Martin and Fitzwater, 1988; Coale *et al.*, 1996; Boyd *et al.*, 2000; Fung *et al.*, 2000]. These Fe-limited HNLC waters comprise ~30% of the world ocean [de Baar and Boyd, 2000] and thus the supply of Fe to the surface waters of the ocean may play a key role in regulating ocean productivity, the atmospheric CO₂ concentration and climate. In fact, the hypothesis that the glacial-interglacial change of atmospheric CO₂ can be attributed to changes in the atmospheric dust-Fe supply to the Southern Ocean (SO) is plausible, albeit controversial [e.g., Martin and Fitzwater, 1988; Watson *et al.*, 2000; Maher and Dennis, 2001; Latimer and Filippelli, 2001; Röthlisberger *et al.*, 2004]. Understanding the biogeochemical cycling of Fe in both present and past climate regimes and the role of mineral dust in Fe-mediated carbon

sequestration in the oceans is one of the most outstanding issues in climate science today [Martin and Fitzwater, 1988; Watson *et al.*, 2000; Maher and Dennis, 2001].

[3] The SO is one of the largest regions [e.g., Fung *et al.*, 2000; Watson, 2001; Coale *et al.*, 2004] of the world ocean where phytoplankton growth rates are limited by micronutrient Fe, although strong grazing pressure, light limitation and silicon limitation have also been suggested [Mitchell *et al.*, 1991; Banse, 1996; Boyd *et al.*, 2001; Coale *et al.*, 2004]. Owing to the large silicic acid gradient in the SO surface waters Fe-enrichment would cause diatoms to bloom to the south of the Antarctic Polar Front Zone (see auxiliary material¹), whereas nonsiliceous phytoplankton species would likely dominate in waters to the north [Coale *et al.*, 2004]. Therefore surface waters in the northern subantarctic region of the SO (with low-silicic acid but high nitrate) are also referred as high-nitrate low-silicic acid low-chlorophyll (HNLSiLC) [Dugdale and Wilkerson, 1998]. Compared to other Fe-limited regions, the SO is thought to receive the lowest flux of atmospheric dust-Fe [Duce and Tindale, 1991] and, as a result, oceanic sources, through the upwelling of deep water, resuspension of sediments, remineralization of sinking material and diffusion from the pore waters have often been proposed to be the likely suppliers of Fe to this region [de Baar *et al.*, 1995; Löscher *et al.*, 1997; Watson, 2001]. However, there has been a growing interest in the possible contribution of

aeolian dust-Fe to the enhancement of phytoplankton stocks and concomitant drawdown of atmospheric CO₂ in this oceanic region [Maher and Dennis, 2001; Latimer and Filippelli, 2001]. Two major source areas for aeolian dust deposited to the SO are arid and semi-arid regions of South America and Australia [Fung et al., 2000; Ginoux et al., 2001; Zender et al., 2003]. Analysis of remotely sensed data of aerosol optical depth and ocean surface chlorophyll concentration [Chl *a*] together with the simulated dust-Fe deposition showed a strong correlation between the atmospheric delivery of mineral dust and phytoplankton growth in surface waters of the SO downwind from the Patagonian and south Australian regions [Gabric et al., 2002; Erickson et al., 2003]. On the basis of this correlation, it has been suggested that phytoplankton productivity in the Antarctic Circumpolar Current (ACC) region of the SO between 40°S and 60°S is controlled by the rate of supply of atmospheric dust-Fe mainly emanating from Patagonia [Erickson et al., 2003].

[4] Studies suggesting a link between mineral dust deposition and productivity in the SO are subject to some uncertainties. (1) The individual dust storm event-based analysis of mineral-Fe supply to the surface waters of the SO provided no compelling evidence for a causal relationship between Australian dust deposition and phytoplankton blooms [Boyd et al., 2004]. (2) The deposition of mineral dust to Fe-limited surface ocean regions does not necessarily initiate a phytoplankton bloom. While mostly dissolved Fe can be used by phytoplankton, virtually all Fe in soils from arid and semi-arid regions is in a crystalline Fe-III form [Claquin et al., 1999], dissolution of which is believed to be negligible in first 24 hours after dust deposition to the ocean surface and extremely low thereafter [Jickells and Spokes, 2001; Bonnet and Guieu, 2004]. It has been shown that dust plumes may not always exhibit enhanced soluble Fe levels relative to nondust days [Meskhidze et al., 2005]. Since Fe-III oxides can be dissolved in acidic solutions, it has been proposed that the fraction of Fe in airborne mineral dust that is mobilized or dissolved (referred to here as the Dissolved Iron Fraction or DIF) during dust transport in the atmosphere can become significant if the dust is sufficiently acidified by the incorporation of sulfuric acid from oxidation of SO₂ [Jickells and Spokes, 2001; Colin et al., 1990; Zhu et al., 1993; Zhuang et al., 1992; Meskhidze et al., 2003]. Meskhidze et al. [2005] recently suggested that the amount of SO₂ entrained from the oxidation of dimethyl sulfide (DMS) alone may not be sufficient to yield the required DIF in dust storms to cause observable changes in marine ecosystem productivity. Considerable amounts of anthropogenic SO₂ mixed with mineral dust may be required to generate large-scale phytoplankton blooms [Meskhidze et al., 2005]. Patagonia, the postulated source region for the dust used for the Fe fertilization of the Atlantic sector of the SO (ASO), is sparsely populated and considered to be one of the most pristine areas of the globe. The amount of SO₂ available for mixing with mineral dust plumes is unlikely to be enough to acidify the dust and solubilize mineral-Fe. (3) Owing to highly dynamic nature of ACC, sampling frequencies significantly higher than the monthly averaged values, used in published mineral dust–phytoplankton growth study [Erickson et al., 2003],

are required to reliably establish a correlation [Meredith and Hughes, 2005]. (4) Mineral dust deposition fluxes and phytoplankton productivity downwind from Patagonia have similar seasonal trends: they both reach their maxima during September to March and diminish during austral fall and winter [Trenberth et al., 1990; Gaiero et al., 2003; Lässig et al., 1999]. Therefore removal of seasonal trends in the temporal anomalies is necessary.

[5] Atmospheric circulation in Patagonia, an extended region of Argentina south of 42°S (Figure 1), is controlled by strong and persistent westerlies [Labraga, 1994] and by the movement of dynamic cyclonic centers [Gaiero et al., 2003; Hoskins and Hodges, 2005]. The low soil water content, sparse vegetation cover and strong surface winds yield significant dust emissions from Patagonia [Ginoux et al., 2001; Zender et al., 2003]. Patagonian dust transport primarily occurs between 40°S and 60°S with the transport path that strongly correlates with the trajectories of cyclonic systems over the Atlantic and Indian Ocean regions of the SO [Hoskins and Hodges, 2005]. The cyclogenesis and prevailing westerly winds that cause dust transport from Patagonia have also been shown to cause strong baroclinic instability in Atlantic and Indian Ocean regions of the SO [Taljaard, 1972; Trenberth, 1991; Nakamura and Shimpou, 2004; Hoskins and Hodges, 2005]. A number of studies of the Southern Hemisphere “storm tracks” show that interaction of dynamic cyclones with baroclinically unstable frontal jets (see auxiliary material) may initiate meandering currents and lead to isolated upwelling and downwelling [Hense et al., 2003]. Owing to the high eastward velocities within the frontal zone, the meanders move eastward with typical wavelength of 160–180 km [Hense et al., 2003]. The vertical velocities in mesoscale upwelling cells in ACC waters range from 5 to 20 m/day, leading to the comparable timescales for transporting cold and nutrient rich waters from below the mixed layer depth (40 to 120 m) and doubling the phytoplankton concentration in surface waters [Hense et al., 2003; Coale et al., 2004]. As eddies contribute to cross frontal and vertical nutrient exchange, they are often assumed to promote phytoplankton growth [e.g., Hense et al., 2003].

[6] To explain the strong correlation between aeolian dust deposition and [Chl *a*] [Erickson et al., 2003], we suggest an existence of atmospheric circulation pattern in the region that simultaneously causes the uplift and transport of mineral dust from Patagonia and an upward supply of nutrient-rich waters from the surface waters of ACC. (Unless otherwise noted, “upwelling” or “upward supply” in this study is thought to primarily occur owing to mesoscale circulation and frontal dynamics along ACC.) Such a mechanism, if it exists, would enhance ocean productivity in the ASO through upwelling but would still exhibit a high correlation between [Chl *a*] and atmospheric dust-Fe flux even if the dust did not contain significant amounts of bioavailable Fe and thus played no actual role in fostering enhanced biological activity in the region. To check the viability of this mechanism we perform statistical analyses of remotely sensed sea surface temperature (SST) and [Chl *a*] data. Because relatively uniform near-surface temperatures in longitudinal direction [Peterson and

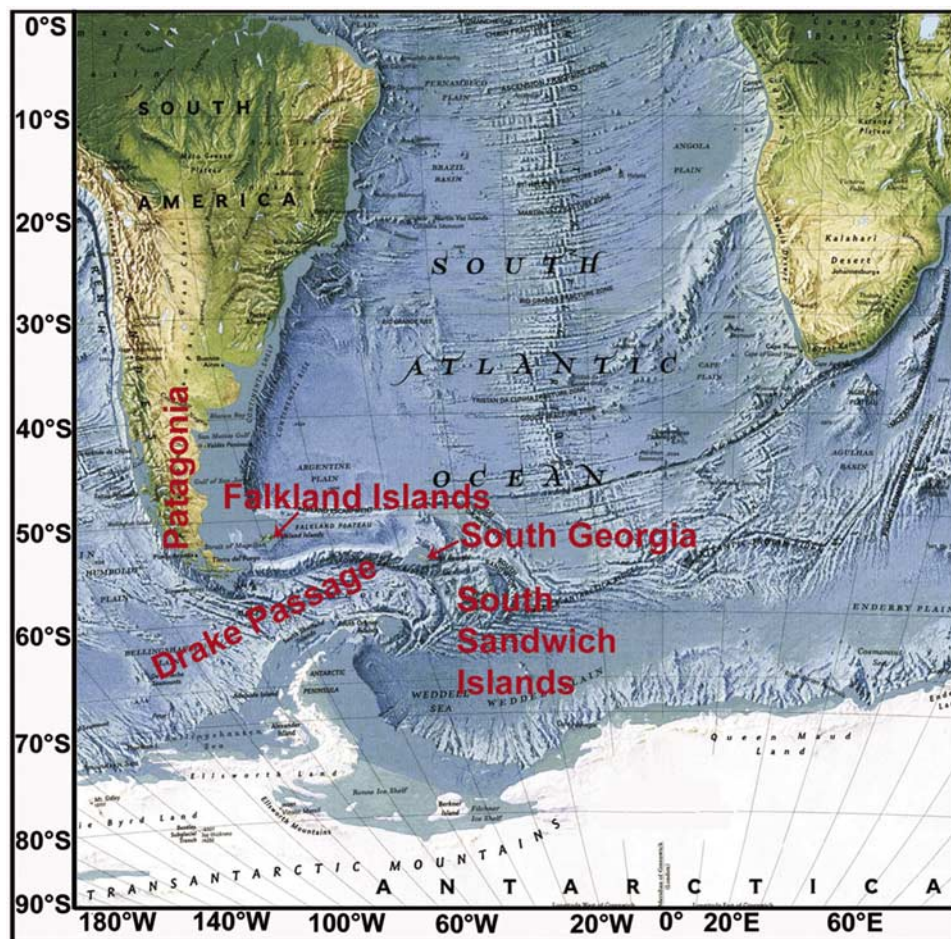

Figure 1. Map of the South Atlantic Ocean (SAO).

Stramma, 1991] and high concentration of nutrients in the deep waters [Martin *et al.*, 1990; de Baar *et al.*, 1995; Löscher *et al.*, 1997], SST anomalies can be used as a proxy for upwelling in ACC; i.e., negative SST anomalies would point to the regions where ocean productivity is likely to be supported by upward supply of relatively cold waters with enriched concentrations of nutrients (e.g., bioavailable Fe). By examining the correlation of the weekly anomalies, we assess the response of [Chl *a*] departures to those of SST (see below). The correlation analyses is carried out in ASO between 20°S to 80°S and 80°W to 40°E (hereinafter referred to as study area) and the relative importance of oceanic and atmospheric sources of Fe are examined in the perspective of conditions needed for mobilization of mineral-Fe into bioavailable form [Meskhidze *et al.*, 2005].

2. Materials and Methods

[7] The 8-day averages of MODIS (Moderate Resolution Imaging Spectroradiometer) remotely sensed SST and [Chl *a*] data with 39 km special resolution (see Supplementary Information) are used to produce weekly anomaly maps. The weekly data was chosen to assure that the [Chl *a*] is not considerably affected by cloud variability, while still allowing the SST signal to retain the characteristics of its origin. Short averaging time also minimizes the wind drift

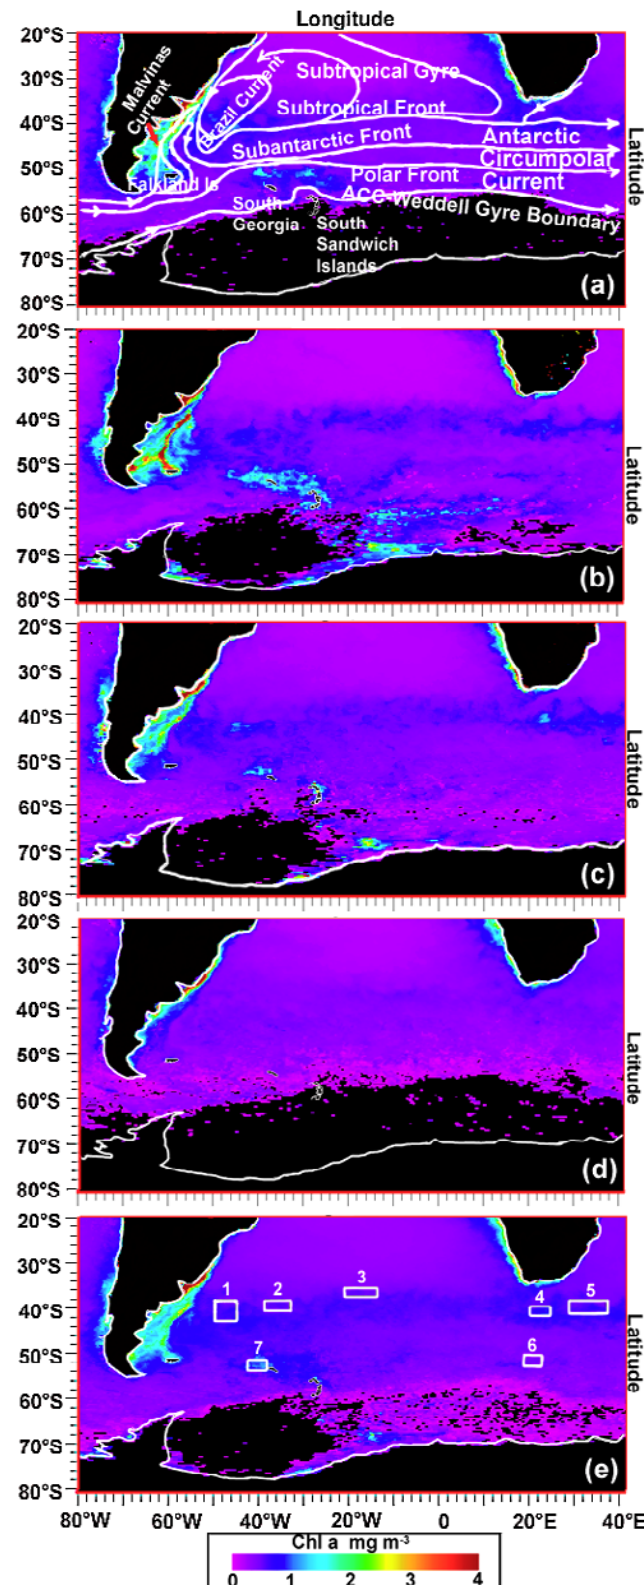

of fertilized water masses. The SST and [Chl *a*] spatial anomalies were computed by subtracting the longitudinally averaged values (over 1° on either side) from the time series of data. The use of longitudinal averages was chosen because both [Chl *a*] and SST are relatively uniform along the ACC fronts. Data points characterizing clouds and continental regions were carefully removed from the analysis. The regions of very low algal biomass are not relevant to the discussion; thus, the correlation coefficient calculations were limited to areas with yearly average [Chl *a*] > 0.2 mg m⁻³. Lower values can also cause anomalous readings in retrievals of phytoplankton biomass [Claustre *et al.*, 2002] and bias our analysis. Total suspended material (TSM) and colored dissolved organic matter (CDOM) in optically complex coastal waters near large river discharge and a relatively shallow seafloor regions (i.e., along the Patagonian coast) may also cause inaccurate retrieval of MODIS [Chl *a*] [Esaias *et al.*, 1998]; therefore results of our analysis in near coastal regions should be regarded with some degree of caution.

3. Results and Discussion

3.1. [Chl *a*] Concentration and the Ocean Circulation

[8] Figure 2 shows seasonal and yearly averaged [Chl *a*] images for the study area downwind from Patagonia.

Figure 2 indicates the appearance of a high $[\text{Chl } a]$ region almost parallel to the Argentine coastline from $\sim 35^\circ\text{S}$ to 50°S as well as elongated west to east streaks downwind from Patagonia. The high $[\text{Chl } a]$ region near the Argentine

coast coincides with the location of the cold and nutrient rich Malvinas Current (see Figure 2a and also auxiliary material Figure S1); mesoscale meandering bands of elevated $[\text{Chl } a]$ downwind from Patagonia seem to be well associated with the upper-level currents in ACC and trajectories of cyclonic systems [Hoskins and Hodges, 2005]. Though $[\text{Chl } a]$ in this regions is not as high as in Malvinas current, elevated marine productivity along the Subtropical Front is clearly visible over the negligible background $[\text{Chl } a]$. The source of the bioavailable Fe causing the enhanced $[\text{Chl } a]$ in remote waters of the SAO cannot be definitively ascertained from Figure 2 alone; however, characteristic geometry of the observed $[\text{Chl } a]$ suggests that upwelling due to the interaction of cyclonic systems with rapidly flowing ACC currents is certainly plausible.

[9] Figure 2 also shows that the waters surrounding South Georgia Island often support large phytoplankton blooms. The regularly observed stimulation of the primary production north of the Island is highly localized and correlates well with the peak frequency of seasonal dust advection off the Patagonian coast (see below). Although enhancement of productivity and biomass near South Georgia Island has been attributed to the “islandmass effect” leading to surface water becoming enriched in nutrients from the island platform [e.g., de Baar *et al.*, 1995], the precise mechanism of bloom formation remains poorly understood [Korb and Whitehouse, 2004] and could be caused by episodic deposition of Patagonian dust. These suppositions are examined statistically below.

3.2. Remotely Sensed SST and $[\text{Chl } a]$ Anomaly Correlation

[10] If enhanced productivity in study area is driven by upwelling of cold and nutrient-rich (e.g., Fe) deep waters from below the euphotic zone, we would expect to find a negative correlation between SST and $[\text{Chl } a]$ anomalies in the region. Comparison of Figures 2 and 3 shows that the regions with elevated $[\text{Chl } a]$ in the remote waters of the SAO also display negative correlation (-0.3 to -0.6) between the SST and $[\text{Chl } a]$ anomaly fields, suggesting that biological activity in ACC is likely to be coupled to upwelling of Fe-rich waters. To get an objective measure of the strength of the correlation, we have chosen several zones in ACC region with elevated $[\text{Chl } a]$ (see Figure 2e), and calculated correlation coefficients for seasonally and yearly averaged SST and $[\text{Chl } a]$ anomaly fields within these zones. Correlations for the seasonal anomalies were calcu-

Figure 2. MODIS-observed $[\text{Chl } a]$ over the Atlantic sector of the Southern Ocean (ASO), averaged for the period from (a) September to November 2002, (b) December 2002 to February 2003, (c) March to May 2003, (d) June to August 2003, and (e) September 2002 to August 2003. The thin white lines indicate the coastal boundary. Thick white lines on Figure 2a denote the large-scale, upper level currents and fronts in the ASO (adapted from Peterson and Stramma [1991]). White squares on Figure 2e show the zones where seasonal variation of SST and $[\text{Chl } a]$ anomaly correlation was calculated.

Figure 3. MODIS-observed yearly averaged (September 2002 to August 2003) SST and [Chl *a*] anomaly correlation for the ASO. The white lines indicate the coastal boundary. Gray color shows the area that was not included in correlation coefficient analysis ([Chl *a*] < 0.2 mg m⁻³).

lated to evaluate the response of [Chl *a*] to changes of SST for the seasonal cycle of the mixed layer depth, wind stress and solar irradiance levels, while yearly anomalies were calculated to assess the long-term relationship between SST and [Chl *a*]. Figure 4 shows that most of the zones display considerable negative correlation between SST and [Chl *a*]. The correlation is typically highest during the austral summer and fall likely caused by the shoaling of mixed layer depth [Hense *et al.*, 2003] and increase in the zonal wind stress [Trenberth *et al.*, 1990], making it easier for nutrients from below euphotic zone to be uplifted to the surface ocean. During austral summer and fall seasons, the SST and solar irradiance levels in ACC are also sufficient for sustaining high rates of photosynthesis [Moore and Abbott, 2002]. The negative correlation between SST and [Chl *a*] shown on Figures 3 and 4 supports the statement that the supply of dissolved Fe to the surface ocean of ACC is most likely from below by upwelling of cold and nutrient rich waters. However, Figures 3 and 4 also show that in the large phytoplankton bloom area near South Georgia Island (zone 7) correlation is insignificant indicating that supply of bioavailable Fe by means other than upwelling of deep ocean waters (i.e., from atmospheric input of Patagonian dust) is plausible and will be discussed in details below.

[11] Examining the time lag between remotely sensed SST and [Chl *a*] data sets provides further support for the deep water enrichment of Fe. It has been shown that primary productivity in an Fe-enriched patch of the ACC waters begins to exhibit a significant increase after several days of an initial infusion and [Chl *a*] levels remain noticeably enhanced for more than a month [Boyd *et al.*, 2000; Abraham *et al.*, 2000; Coale *et al.*, 2004]. If the enhanced [Chl *a*] is caused by the upwelled nutrients, as the

rapid eastward flow in ACC moves the fertilized water masses away from the area of the enrichment, it is expected to see considerable decorrelation of SST and [Chl *a*] anomaly fields when time delay between two fields increases over several weeks. However, if [Chl *a*] increase is caused by deposition of mineral dust, assuming that dust is not preferentially deposited in the upwelling zones, there should be no significant change in the observed SST–[Chl *a*] correlation image with the time evolution. Figures 5a and 5b show that the correlation between two fields is typically high when the time delay between SST and [Chl *a*] is less than two weeks and diminishes as the delay increases further. More importantly, when the time series for [Chl *a*] are shifted behind of SST by more than one month, the correlation between the two fields virtually disappears (Figure 5c).

[12] Despite capturing some main features of phytoplankton distribution in study area, Figures 3 and 4 show that negative correlation between SST and [Chl *a*] is not strong in all parts of ACC with elevated [Chl *a*]. The extensive cloud cover over the Southern Ocean is one of the factors that can significantly weaken the correlation between remotely sensed fields. Since sea surface temperature is retrieved at night as well as during the day SST coverage is generally better than ocean color data, which can only be collected during daylight hours. Although SST and [Chl *a*] data used in correlation analysis are from the same week, depending on cloud cover, parameters chosen for the weekly averages may be from different days. The correlation is farther hampered by geostrophic transport along the frontal jets [Strass *et al.*, 2002]; simulations of the regional ecosystem dynamics in the ACC show (in agreement with observations [Strass *et al.*, 2002]) that in the meandering current, low phytoplankton concentrations can coincide

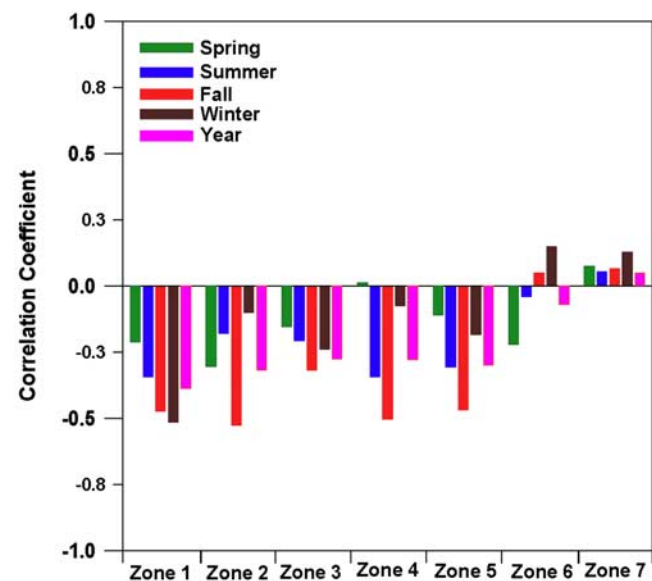

Figure 4. Correlation coefficient for seasonally and yearly averaged MODIS-observed SST and [Chl *a*] anomaly correlation for the selected zones (see Figure 2e) in ASO.

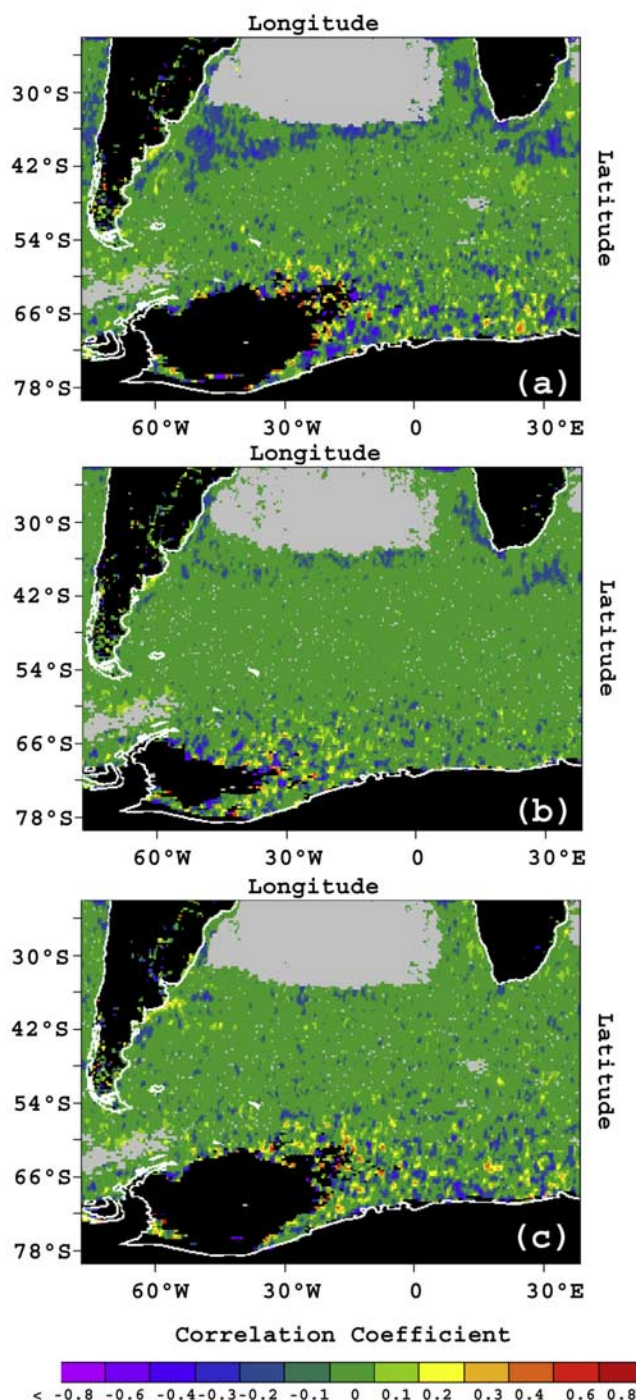

Figure 5. Same as for Figure 3, but with time series of [Chl *a*] shifted behind of SST by (a) 8 days, (b) 16 days, and (c) 32 days.

with upwelling spots, whereas maximum [Chl *a*] concentrations can occasionally occur in downwelling areas [Hense *et al.*, 2003]. Eddies and cross-frontal circulation, sporadically produced by baroclinic instability along frontal currents can lead to redistribution of major nutrients and phytoplankton between surface and deep ocean. Newly

upwelled water near the surface has low [Chl *a*], but is rich in nutrients and therefore can sustain phytoplankton growth during its advection, until water is downwelled on the side of the meander ridge [Hense *et al.*, 2003]. If horizontal advection in ACC currents is fast enough to move the fertilized water masses outside of the MODIS observed grid domain, it can significantly lessen negative correlation between SST and [Chl *a*] and even reverse its sign. Other factors such as silicic acid, light limitations and the grazing pressure may also be significant at times. Therefore highly complex behavior of ecosystem dynamics in ACC region cannot be fully resolved by remotely sensed data; instead, in situ observations and comprehensive three-dimensional ocean-plankton models are required to fully account for the surface ocean–chlorophyll dynamics [Hense *et al.*, 2003; Pollard *et al.*, 2002].

[13] The absence of correlation between SST and [Chl *a*] signals in the large phytoplankton bloom area close to South Georgia Island (zone 7 on Figure 2a) can be explained by considering possible mechanisms for the bloom formation in these waters. Korb and Whitehouse [2004] suggest that anticyclonic circulation near South Georgia is capable of enriching the surface waters by sedimentary micronutrients (e.g., Fe) from the bottom waters and the island's shelf. Reduced surface mixing and the retention of water near the surface caused by anticyclonic circulation can also result in stability and elevated temperatures initiating large phytoplankton blooms [Meredith *et al.*, 2003; Korb and Whitehouse, 2004]. Such mechanisms of bloom formation are not captured by the objective analysis used here and therefore, display no significant correlation between SST and [Chl *a*] anomalies in this region (Figure 3).

3.3. Large Bloom in the South Georgia Region

[14] As the precise mechanism for the bloom formation near South Georgia Island remains poorly understood [Korb and Whitehouse, 2004], we test the potential role of Patagonian dust deposition in the observed blooms. Figure 6 illustrates MODIS observed [Chl *a*] concentrations downwind from the Island and MATCH (Model of Atmospheric Transport and Chemistry) [Rasch *et al.*, 1997; Mahowald *et al.*, 1997] calculated fluxes of mineral dust (see also auxiliary materials Figures S2 and S3). Although increase of biological activity in this region is a regular phenomenon with similar seasonal trend as Patagonian dust deposition (Figure 6), there is significant variation in the bloom's temporal appearance, spatial extent and strength that cannot be accounted by the variation in mineral dust. Large atmospheric dust fluxes in year 2000 did not cause significant change of [Chl *a*] in this region, while years 2001 and 2004 with moderate dust deposition were characterized by massive blooms. Although these results cannot be considered conclusive because MATCH results have not been tested extensively against surface observations in the Southern Hemisphere [Luo *et al.*, 2003], they are suggestive that dust deposition is not a major controlling factor of enhanced productivity near South Georgia Island. Nevertheless, the detailed analyses of hydrographic data concurrently with in situ studies of mineral dust composition and soluble Fe fraction may be necessary to unambiguously identify the sources of bioavailable Fe and

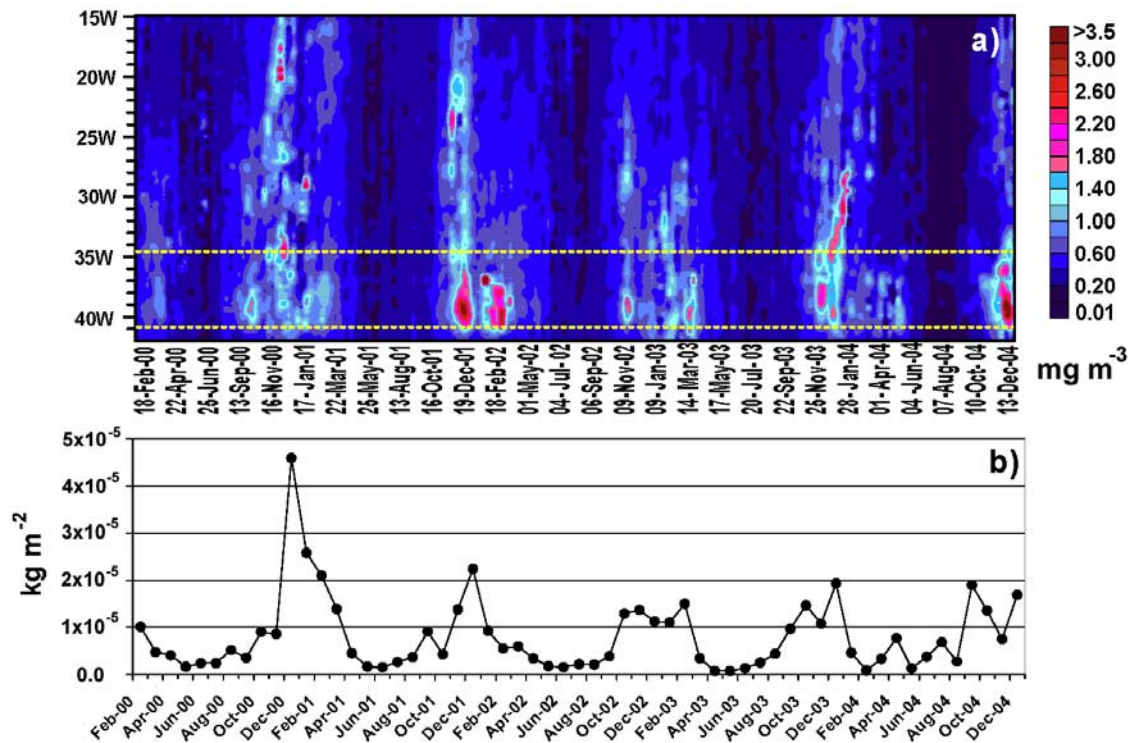

Figure 6. (a) Latitudinally averaged (49°S to 54°S) MODIS-observed [Chl *a*] and (b) model-predicted monthly averaged fluxes of mineral dust near South Georgia Island (49°S – 54°S , 35°W – 41°W). Horizontal dashed lines indicate the approximate area near the Island where the dust fluxes are averaged.

their controls on biological productivity near South Georgia Island.

4. Possible Implications to Carbon Cycle in the ASO

[15] Analysis of remotely sensed MODIS data shows significant negative correlation (-0.3 to -0.6) between SST and [Chl *a*] spatial anomalies in study area of the SAO. Since SST anomalies in this region can be used as a proxy for upwelled nutrients (e.g., Fe), these correlations are likely to be indicative of a causal relationship between upwelling of nutrient-rich waters and ocean productivity in ASO. This result is consistent with our earlier studies supporting the hypothesis that substantial acidification of aeolian dust prior to its deposition to the ocean may be required to solubilize the large fraction of mineral-iron and make it bioavailable [Duce and Tindale, 1991; Zhuang *et al.*, 1992; Zhu *et al.*, 1993; Spokes and Jickells, 1996; Desboeufs *et al.*, 2001; Meskhidze *et al.*, 2003, 2005]. In conjunction with previously shown high correlation between mineral dust-Fe deposition and [Chl *a*] [Erickson *et al.*, 2003], results of this study suggest the existence of a meteorological mechanism that simultaneously uplifts and transports mineral dust from Patagonia and drives deep-water upwelling of nutrients (e.g., dissolved Fe) to the surface waters of the ASO.

[16] To the extent that biological activity in this region plays an important role in global carbon cycle, the results presented in this study in conjunction with our previous analysis of mineral dust transport [Meskhidze *et al.*, 2005] suggest that mere changes in the dust-Fe supply (perhaps without significant increase in sulfur sources) may not exert considerable influence on the drawdown of atmospheric CO_2 in the ASO. Therefore, if past changes in the supply of bioavailable Fe to the ASO have played nontrivial role in determining the atmospheric CO_2 , the hypothesis about the required acidity for dissolving significant fraction of mineral iron in dust may prove to be invaluable in understanding the dynamics of the past climate.
